ABSTRACT

A total of 60 fresh-water fish were obtained from a local fish breeding center and carefully transported in plastic bags having adequate amount of oxygen and water. After 7 days of acclimatization, all the fish were randomly divided and kept in five equal groups (A-E). The experimental fish were exposed to various concentrations (0, 0.5, 1.0, 1.5 and 2.0 mg/L) of thiamethoxam for a period of 120 h. Blood and other tissue samples of each treated fish were collected after 72, 96 and 120 h. Various physical responses like operculum and bouncing movement, mucus secretion, darkening of fins, fin tremors, swimming in isolation on one side, surface breathing and erratic swimming were observed in fish treated with higher concentrations. Results indicated that the values of red blood cell counts (RBCs), packed cell volume (PCV) and hemoglobin (Hb) concentrations were significantly lower and white blood cell (WBCs) and neutrophil counts increased significantly in thiamethoxam treated fish as compared to unexposed fish. The frequency of various nuclear (micronuclei, erythrocytes with nuclear remnant, erythrocytes with condensed nuclei and erythrocytes without nucleus) and morphological changes (leptocytes, stomatocytes, dividing erythrocytes and tear shape erythrocyte) in treated fish was significantly higher as compared to control group. Microscopic analysis of gills tissues of various experimental fish exhibited atrophy of secondary lamellae, pyknosis of lamellar epithelial pillar cells, lamellar degeneration, congestion, aneurysm and curling of lamellae.

INTRODUCTION

Contamination with poisonous compounds such as pesticides, trace metal, heavy metals, polycyclic aromatic hydrocarbons and polycyclic aliphatic hydrocarbons and numerous other effluents causes varieties of adverse impacts on living organisms leading to considerable population damage. The development and advancement in technology, industries and common use of numerous synthetic and natural compounds have led to contamination of aquatic ecosystems (Ghaffar *et al.*, 2015a; Ghaffar *et al.*, 2016). Among different synthetic

compounds, pesticides are extensively and frequently used in modern agriculture, public health and veterinary practice to remove insects (Hussain *et al.*, 2014). The pesticides cause harmful and deleterious effects on both terrestrial and aquatic ecosystems (Hussain *et al.*, 2015; Gul *et al.*, 2017). Agricultural and industrial routes are continuously releasing their toxic chemicals as waste products which not only contaminate the aquatic biota but also cause numerous tissue changes in variety of exposed organisms (Witeska *et al.*, 2014; Qureshi *et al.*, 2016). Thiamethoxam being a neonicotinoid insecticide is frequently used in agriculture to protect variety of food

crops including cotton fields and paddy fields to control pests (whiteflies, aphids and leafhoppers (Gul *et al.*, 2017). Neonicotinoid insecticides (thiamethoxam) obstruct the acetylcholine receptors, therefore disturbing the central nervous system activities leading to death of insects (Green *et al.*, 2005; Shalabey *et al.*, 2010). Recent studies have indicated that among different neonicotinoids, the thiamethoxam is widely used due to its selectivity (Al-Kherb, 2011) against different pests across the globe and affects development, reproductive system and immunity by causing morphological, pathological and physiological changes in non-target organisms (Mason *et al.*, 2013; Thaker, 2014; Ugurlu *et al.*, 2015). Different environmental pollutants particularly pesticides/heavy metal have been linked to cause adverse effects such as apoptosis, poor fertilization, abnormal spermatogenesis, DNA fragmentation, mitochondrial dysfunctions through ROS-scavenging antioxidants depletion in various target and non-target organisms ranging from aquatic life to humans (Khan *et al.*, 2015; Ghaffar *et al.*, 2017a). Aquatic ecosystems are the ultimate basins for agricultural residues as well industrial pollutants (Gupta *et al.*, 2014). Among all aquatic animals, fish are sensitive to water pollution. In fish, different toxicants are mainly absorbed through the gills, skin or alimentary duct and diffuse into different tissues resulting to disruption of physiological and biochemical processes (Qureshi *et al.*, 2016). It is reported that the sub lethal concentrations of pesticides in aquatic environment induces abnormal metabolisms and changes in behavior and death of aquatic organisms. Monitoring and determination of different adverse effects particularly genotoxicity of pesticides in exposed and non-target species is sensitive and reliable end point (Khan *et al.*, 2015; Ghaffar *et al.*, 2016). Different important biomarkers attract huge attention in screenings of various compounds in environmental studies as a sensitive tool for evaluation and detection of effects of pollutants from natural and anthropogenic sources (Kostić *et al.*, 2017). Therefore, this study aimed at to investigate the effects of thiamethoxam considering DNA damage and histopathological examination of gills as sensitive biomarkers in fresh-water fish.

MATERIALS AND METHODS

Experimental fish and management: The experimental research was planned and conducted at laboratories of Department of Life Sciences (Toxicology and aquaculture laboratory) and Veterinary Sciences (Pathology), Islamia University of Bahawalpur. A total of 60 fresh-water fish were purchased from local fish breeding center Hasilpur. All the experimental fish were carefully transported in plastic bags having adequate amount of oxygen and water. The fish were kept in glass aquaria and handled according to guidelines of Scientific Ethic Committee of Islamia University of Bahawalpur.

Apparently healthy and active fish (n=60) of same weight, age and size were kept in glass aquaria about 64×32×34 cm containing 100 L water capacity and equipped with oxygenators. All the fish were left to acclimatize for 7 days. After seven days of acclimatization the experimental fish were randomly separated into five groups A, B, C, D and E. Fish present in group served as

control group. Different doses of thiamethoxam were given to all remaining groups. All the experimental test specimens in various groups were exposed to different concentrations (0.5, 1.0, 1.5 and 2.0 mg/L) of thiamethoxam were to groups (B, C, D and E) respectively for a period of 120 h. Clinical signs, behavioral changes and mortality were monitored throughout the experiment.

Hematobiochemical parameters: Blood samples with and without anticoagulant were collected after 72, 96 and 120 h of treatments from caudal vein by using 26-gauge hypodermic needle. For morphological and nuclear changes in erythrocyte of exposed fish a fine thin blood smear on microscopic slide was prepared from fresh blood of each fish separately. All the blood smears were fixed with absolute alcohol and stained with Giemsa solution. After that they were examined under microscope and photographed. Blood with anticoagulant was processed for hematology. About 5 ml of blood was collected in the clean glass test tube with an anticoagulant. All the collected blood samples were used to determine total red blood cell counts, total and differential leukocyte counts and packed cell volume (Ghaffar *et al.*, 2016).

Histopathology: For histopathological changes, gills were quickly removed from fish, rinsed in isotonic saline solution and fixed in 10% neutral buffered formaldehyde (pH 7.2) solution. After fixation, tissues were dehydrated in ascending series of alcoholic solutions and embedded in paraffin wax. Sections of 4-5µm thickness were cut on a rotary microtome (Shandon Finesse, Italy) and dried on a slide warmer at 37°C. The tissues were deparaffinized in xylene and dehydrated in ascending series of alcohol. Sections were stained with standard hematoxylin and eosin (H& E) method. Sections were finally cleared in xylene and mounted in DPX mountant medium. Multiple sections of each test specimen were observed under a light microscope (Leica, Germany).

Statistical analysis: Data obtained in this experiment were subjected to statistical analysis (SAS, 2004). Means±SE values for hematological and nuclear changes indifferent treatment groups were compared by Tukey's test. Significant difference was accepted at P<0.05 in all cases.

RESULTS

Physical and blood biochemical responses: No mortality and behavioral abnormalities were recorded in untreated fish. Fish received higher concentrations of thiamethoxam showed different physical responses like bouncing movement, darkening of fins, fin tremors, swimming on one side, operculum movement, mucus secretion and surface breathing. Bouncing movement, swimming in isolation and erratic swimming were the characteristic clinical features examined in fish treated with higher concentrations pesticide (1.5, 2.0 mg/L). The results on different blood parameters indicate that the values of red blood cell counts (RBCs) were significantly decreased in pesticide treated fish after 96 and 120 h in groups D and F as compared to unexposed fish (Table 1). The packed cell volume (PCV) and hemoglobin (Hb)

concentrations decreased significantly in group F after 96 h while in groups D and F after 120 h when compared to non-treated fish. The white blood cell (WBCs) and neutrophil counts increased significantly in fish of group F after 72 h while in groups D-F after 96 and 120 h of treatment. The lymphocyte population decreased significantly in fish of group F after 72 and 96 h while in groups D-F after 120 h of treatment as compared to non-treated fish. The monocyte population decreased significantly after 96 h of treatment in fish of group F and in groups E-F after 120 h when compared to non-treated fish.

Genotoxic and morphological changes: The frequency of DNA damage (micronuclei) and different nuclear abnormalities in erythrocyte of pesticide-treated fish is presented in Table 2. Results indicate that the rate of micronuclei, erythrocytes with nuclear remnant and erythrocytes without nucleus increased significantly in group F after 72 and in groups E-F after 96 and 120 h of treatment (Fig.1). The rate of notched nuclei increased significantly in groups E-F throughout the experimental when compared to untreated fish. The rate of condensed nuclei was significantly higher in fish of groups E-F after 72 and 96 h while in groups D-F after 120 h of treatment. The frequency of vacuolated erythrocyte, leptocytes and tear shape erythrocyte was significantly higher in fish of group F after 72 h while in groups E-F after 96 h and in groups D-F after 120 h of treatment as compared to non-treated fish (Table 3). The frequency of stomatocytes and dividing erythrocytes increased significantly in fish of group F after 72 h while in groups E-F after 96 and 120 h of treatment.

Histopathological changes in gills: Histological examination of gill tissue of control fish showed normal arrangements of primary and secondary lamellae (Fig. 2). Gill tissues in treated fish in groups (D and E) after 96 h of treatment presented prominent histopathological changes including atrophy of secondary lamellae, pyknosis of lamellar epithelial pillar cells, disruption and

disorganization of primary and secondary lamellae, lamellar degeneration, congestion, aneurysm and curling of secondary lamellae. Moderate histopathological changes like degeneration, curling and sloughing of lamellar epithelium were observed in gill tissues of fish of group C after 120 h of exposure.

DISCUSSION

Although no mortality was recorded in treated fish in all experimental groups but exposure of thiamethoxam induced different behavioral changes viz., bouncing movement, erratic swimming, darkening of fins, fin tremors, swimming on one side, operculum movement, increased mucus secretion and swimming in isolation. The clinical and behavioral changes in thiamethoxam treated fish might be due to toxic effects. Previous no report could be found in published literature about the clinical signs and behavioral changes in thiamethoxam treated fish. However, it is reported that neonicotinoids pesticides cause poor growth in both in fry in and adult fish (Hayasaka *et al.*, 2012; Gibbons *et al.*, 2014). Clinical signs like operculum and bouncing movement could be due to inhibition of acetylcholinesterase in treated fish. Previously it is well known that thiamethoxam lowers the activity of acetylcholinesterase and causes adverse consequences in fresh-water fish (Clasen *et al.*, 2018). Moreover, different adverse effects including behavioral disorders in offspring of rats (Gu *et al.*, 2013) and incoordination, reduced movement, cessation of feeding and chick developmental abnormalities in birds have also been reported due to neonicotinoid pesticides such as imidacloprid and fipronil pesticides (Gibbons *et al.*, 2014). In current experimental study, all the hematological changes in treated fish occurred in dose depended mode. Significant decrease in red blood cell counts, hematocrit, hemoglobin concentration, monocyte and lymphocyte while increased values of white blood cell count and neutrophil were observed treated fish. It is reported that the monitoring of functions of hematopoietic

organs and different blood parameters are important and considered as the biomarkers for screening of different toxicants and determination of pathophysiological status of organisms exposed organisms (Roy and Nath, 2011; Ghaffar *et al.*, 2016). The significant decreased red blood cell counts and hemoglobin levels in thiamethoxam treated fish could be due to poor efficiency of fresh-water

fish to deliver enough oxygen to blood forming tissues (Hussain *et al.*, 2014; Ghaffar *et al.*, 2017b). Furthermore, lower values of red blood cell and hemoglobin levels can also be due to fatigue metabolic activities and inefficiency of hemopoietic tissues in pesticide treated fish (Ghaffar *et al.*, 2015b). Previously, significantly reduced hematological values in thiamethoxam treated birds (Gul

et al., 2017) and *Oreochromis niloticus* (Trewavas) have also been reported (Roy and Nath, 2011). The lower values of red blood cell count and hemoglobin concentrations might also be due to insufficient exchange of gasses by gills (Osman *et al.*, 2009). The significant increased white blood cell counts and lower values of monocyte and lymphocyte population in treated fish could be due to injurious stimulation of thiamethoxam and the sensitivity of immune system.

Different nuclear (micro nuclei, erythrocytes with nuclear remnants, erythrocyte with blebbed nuclei, erythrocytes without nucleus, notched nucleus, condensed nuclei) and morphological (vacuolated erythrocytes, leptocytes, stomatocytes, dividing erythrocytes, tear shape erythrocyte) abnormalities in erythrocytes of thiamethoxam treated fish were observed. Previously, in published literature no report is available about the nuclear and morphological changes in fresh-water fish exposed to thiamethoxam. The nuclear changes in

erythrocyte might be due to increased induction of oxidative stress and caspase-activated DNase activation leading to mitochondrial damage (Campos-Pereira *et al.*, 2012; Yan *et al.*, 2016; Hussain *et al.*, 2017). Previously, different studies have reported nuclear and morphological alterations like micronuclei, nuclear condensation, erythrocyte swelling, lobed nuclei, irregular shape of nucleus and deterioration of cell membrane due to different toxicants in exposed species including fish (Strunjak-Perovic *et al.*, 2010; Gibbons *et al.*, 2014; Ghaffar *et al.*, 2015b). Moreover, various morphological changes in erythrocyte of treated fish can be due to higher erythropoiesis to compensate the impaired functions and lipid per oxidation (Witeska *et al.*, 2014; Gibbons *et al.*, 2014). Increased DNA breaks in birds due to pesticide has also been reported (Tokumoto *et al.*, 2013). Histologically, gills sections from treated fish exhibited atrophy of secondary lamellae, pyknosis of lamellar epithelial pillar cells, disruption and disorganization of

primary and secondary lamellae, lamellar degeneration, congestion, aneurysm and curling of secondary lamellae. The histological changes in gills of exposed fish could be due to increased lipid peroxidation, catalase activity and glutathione S-transferase levels gills (Yan *et al.*, 2016). Previously, increased protein oxidation, vacuolization and hemostatic infiltration in gills of *Gammarus kischineffensis* and zebrafish exposed to thiamethoxam has been reported (Ugurlu *et al.*, 2015; Clasen *et al.*, 2018).

Conclusions: Based on results of current experimental study, it can be concluded that thiamethoxam even at relevant environmental concentrations causes hematological, genotoxic and histopathological changes in fresh-water fish in a time and dose related manner.

Authors contribution: RH, AG, SN, AK, MKK and IRC planned and executed the research. AG, RH, GA, FA and KA were involved in statistical analysis. RH, MU, ZA and NA prepared the manuscript.
